Esophageal bronchogenic cyst: an uncommon cause of dysphagia in adults. Case report and literature review

Quiste broncogénico esofágico: una causa poco común de disfagia en adultos. Reporte de caso y revisión de la literatura

Abstract

Background: Bronchogenic cysts result from abnormal budding of the primitive tracheobronchial tube and are rare congenital cystic lesions. The location of the cyst depends on the embryological stage of abnormal budding. Although periesophageal bronchogenic cysts have been frequently reported, a completely intramural cyst is very rare. Clinical case: A 42-year-old female patient, a three-month course with retrosternal pain associated with food intake, accompanied by intermittent dysphagia to solids. Esophagogram, high resolution thoracic tomography and endoscopic ultrasound are performed, concluding a probable esophageal bronchogenic cyst. Resection is performed by video-assisted thoracic surgery, without complications. Patient presents with adequate evolution and complete remission of the symptomatology. Conclusion: Bronchogenic cysts of the esophageal wall are extremely uncommon lesions. Its surgical treatment is indicated to be symptomatic; video-assisted thoracoscopic surgery resection is of choice, with excellent long-term results and minimal morbidity.

Resumen

Antecedentes: Los quistes broncogénicos son lesiones congénitas raras que resultan de brotes anormales del tubo tráqueobronquial primitivo. La localización del quiste depende de la etapa embriológica del brote anormal. Aunque los quistes broncogénicos periesofágicos han sido frecuentemente reportados, un quiste completamente intramural es muy raro. Caso clínico: Mujer de 42 años con cuadro de 3 meses de evolución, con dolor retroesternal asociado a la ingestión de alimentos, acompañado de disfagia intermitente a sólidos. Se realiza esofagograma, tomografía de tórax de alta resolución y ultrasonido endoscópico, que concluyen probable quiste broncogénico esofágico. Se realiza resección por cirugía torácica videoasistida, sin complicaciones. La paciente cursa con adecuada evolución y remisión completa de la sintomatología. Conclusión: Los quistes broncogénicos de la pared esofágica son lesiones extremadamente poco comunes. Está indicado su tratamiento quirúrgico al ser sintomáticos; es de elección la resección por cirugía torácica videoasistida, con excelentes resultados a largo plazo y mínima morbilidad.

Background

Bronchogenic cysts are rare congenital lesions that result from abnormal budding of the primitive tracheobronchial tube. The location of the cyst depends on abnormal budding embryological stage.

Approximately 36-90% of bronchogenic cysts occur in the mediastinum, and most of the remaining cysts involve the lung parenchyma. Esophageal bronchogenic cysts are rare; paraesophageal cysts are the most typically reported, and completely intramural cysts are quite rare. Intramural esophageal bronchogenic cysts have only been described in 23 adult cases since 1981.

Most patients are newborns or infants at presentation. The symptoms are usually caused by intrathoracic structures compression, with predominant respiratory problems. Primary symptoms consist of retrosternal pain, cough, dyspnea or fever.

As for the treatment of esophageal bronchogenic cysts, complete surgical resection is recommended by means of thoracotomy or video-assisted thoracic surgery. Some authors recommend it even when patients are asymptomatic, due to later complications such as infection, rupture, intracystic hemorrhage or carcinomatous changes.

Objective

To describe a rare case of a bronchogenic cyst of the esophageal wall diagnosed in adulthood, which was treated with video-assisted thoracic surgery resection, as well as to perform a literature review.

Clinical case

This is the case of a 42-year-old woman. She denied having any chronic-degenerative disease and had a surgical history of two cesarean sections and bilateral tubal occlusion, with no other data of relevance. At admission, she had a 3-month history of retrosternal pain associated with food intake, accompanied by intermittent dysphagia to solids.

As part of her diagnostic workup, she underwent an esophagography, high-resolution chest tomography and endoscopic ultrasound. The esophagography showed extrinsic compression in the middle third of the esophagus (Fig. 1). Chest tomography documented a mass attached at the middle third of the esophagus, which pushed the trachea and aorta (Fig. 2). Endoscopic ultrasound reported a cystic lesion at between 26 and 31 cm from the dental arch, which measured 39 × 30 mm in diameter, with anechoic, discretely turbid content, arising from the esophageal wall and growing inwards covered by normal esophageal mucosa and outwards pushing the trachea and aorta, as well as an adenopathy in the sub-carinal region. Differential diagnosis was probable bronchogenic cyst vs. duplication cyst (Fig. 3).

Performing a resection by video-assisted thoracic surgery was decided, which revealed a 30 × 30 mm lesion on the left lateral side of the esophagus, at the middle third (Fig. 4), with histopathological report of bronchogenic cyst (Fig. 5). The patient had an adequate postsurgical evolution, with incidence of pneumothorax after removal of the endopleural catheter, which was replaced and then successfully withdrawn. The patient was discharged home in appropriate conditions and with complete symptom remission.

Discussion

Bronchogenic cysts are bronchopulmonary foregut abnormalities that usually occur along the tracheobronchial...
Bronchogenic cysts develop when abnormal budding occurs in the laryngotracheal groove after the third week of gestation. Histologically, bronchogenic cysts are characterized by the presence of ciliated cylindrical epithelium and various components of smooth muscle, bronchial gland, cartilage and even pulmonary alveoli in the cyst wall, depending on the stage of gestation at which abnormal budding occurs.

When present, symptoms are usually caused by compression of the surrounding structures or by complications related to the cyst. The most common complications are intracystic hemorrhage, infection, inflammation, ulceration of the cyst, and rupture or perforation of the cyst in the tracheobronchial tree, pericardium or pleura. A mediastinal cystic mass of 3-4 cm adjacent to the esophagus that occurs with dysphagia and chest pain is highly suggestive of a bronchogenic cyst.

Different imaging techniques help locate the anomaly and detect any associated lesion. Postero-anterior and lateral chest X-ray, which is the primary diagnostic modality, can demonstrate the location of the cyst, its size and contours, and especially can show air-fluid levels in the cyst. Contrast esophagography can show if there is communication between the cyst and the esophagus, or reveal only extrinsic smooth compression and displacement of the esophagus. Computed tomography is useful to evaluate the cystic nature of the mass, showing an almost watery homogeneous...
density; it can indicate the exact location of the mass and its relationship with other thoracic structures. However, if the cyst is infected or has protein and calcium high content, its density may fall within the range of solid tissue, which increases diagnostic uncertainty. Definitive diagnosis is established after surgical excision with histological confirmation.

Magnetic resonance imaging is sensitive to detect tissue filled with fluid. However, many bronchogenic cysts contain large amounts of protein material, thus producing hyperintense T1-weighted images, which makes it difficult to differentiate fatty lesions. Endoscopy is carried out to rule out the presence of malignancy. Endoscopic ultrasound is useful for diagnosing intramural esophageal bronchogenic cysts, through a clear delimitation of the submucosal location of the cyst.

The treatment of bronchogenic cysts remains controversial. If the cyst is symptomatic, conventional or thoracoscopic enucleation can be performed. The purpose of surgery is diagnosis, resection and prevention of complications. Video-assisted thoracoscopic surgery is a less invasive option, but with a complication rate of 10-30%. Alternatives to surgery include transesophageal needle aspiration, and even a successful long-term results and minimal morbidity.
